

The Time History of Planet Formation: Observation Confronts Theory

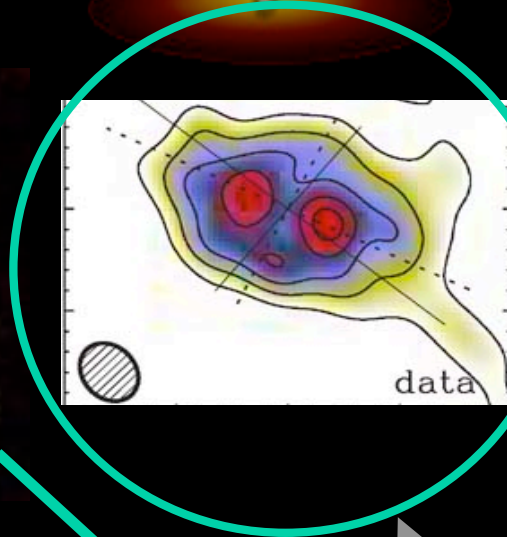

Thayne Currie (CfA/NASA-Goddard)

Issues to Address in this Talk

Protoplanetary

Debris

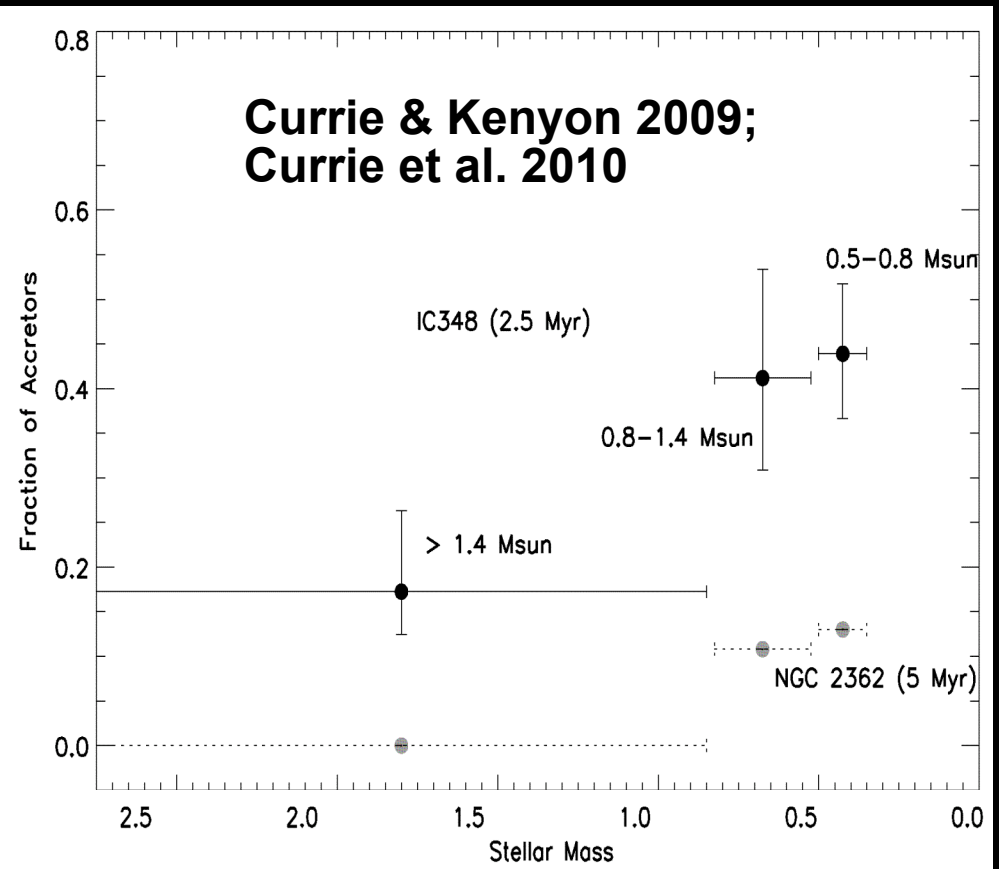

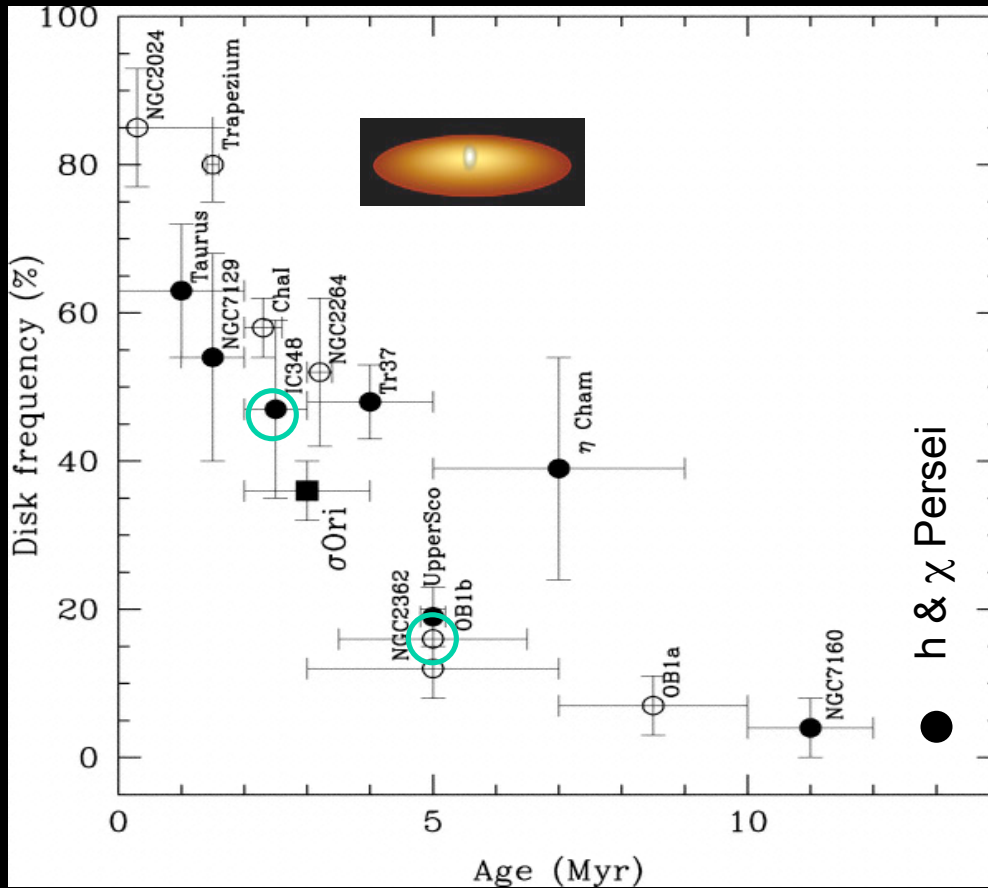

1. Timescales for Protoplanetary Disk Evolution/Gas Giant Planet Formation

2. Nature of Transitional Disks/late-stage Protoplanetary Disk
3a. Debris Disk Evolution and initial planetesimal sizes

3b. Debris Disk Evolution → stages in planet formation

1a. Protoplanetary Disk Evolution

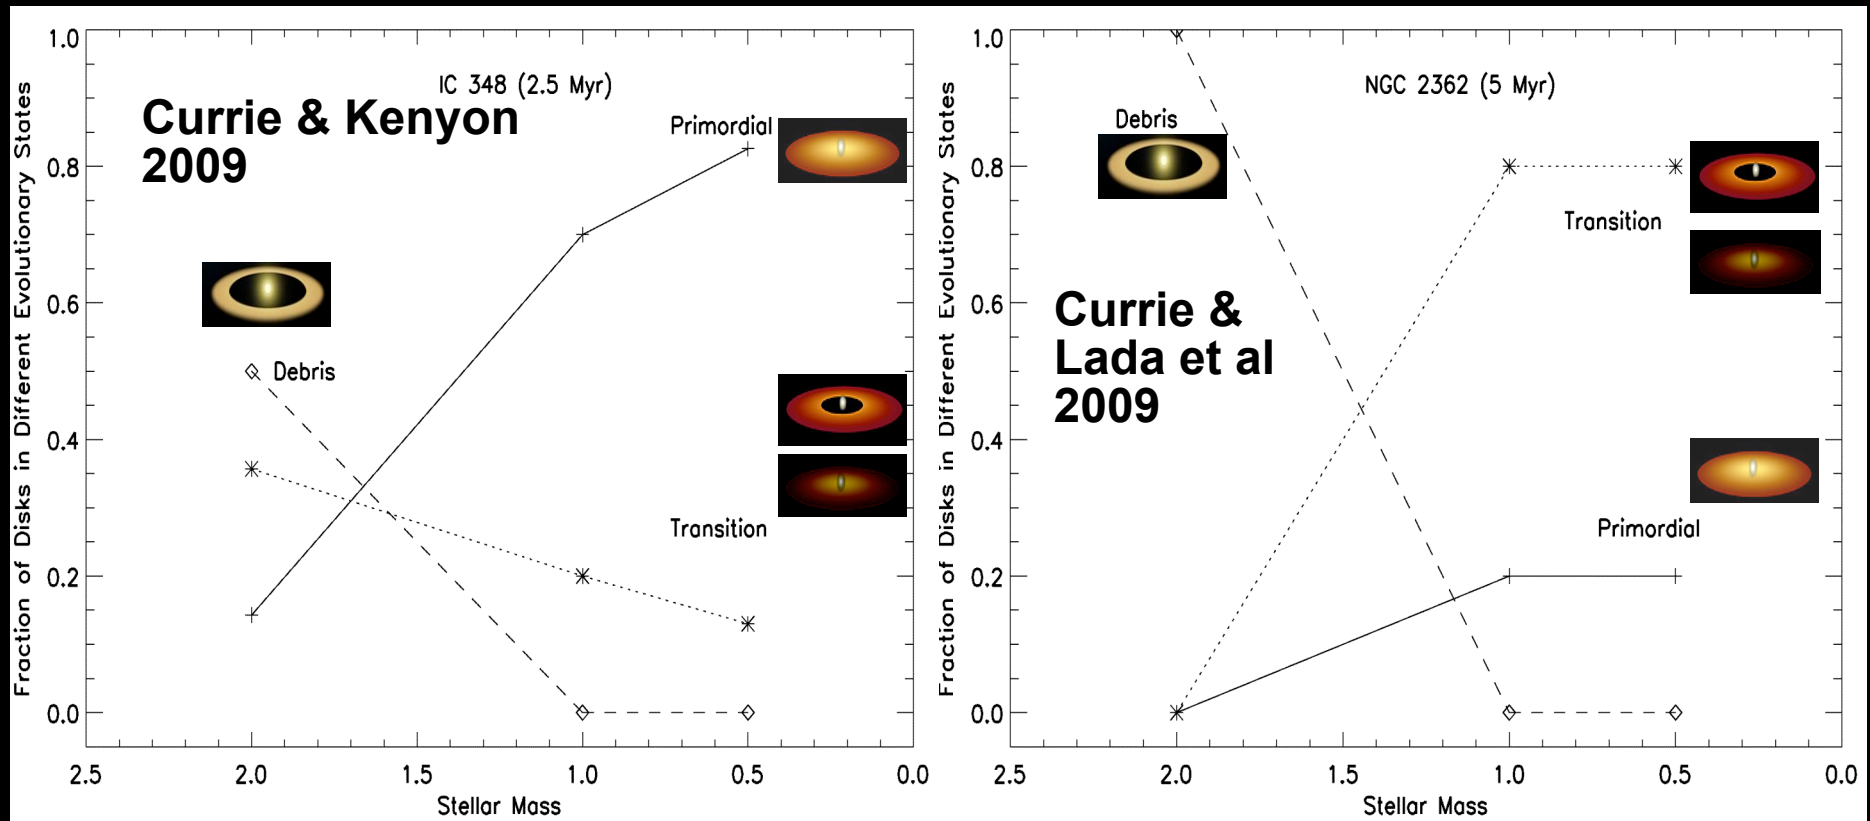

Warm primordial (protoplanetary) disk material gone by ~5 Myr for most stars (Hernandez et al. 2007; Currie et al. 2010)

Signatures of warm gas gone by 2.5 Myr for A stars; 5 Myr for solar/subsolar mass stars

Now compare frequency of disks that are

- 1) primordial, 
- 2) nal, 

1b. Protoplanetary Disk Evolution

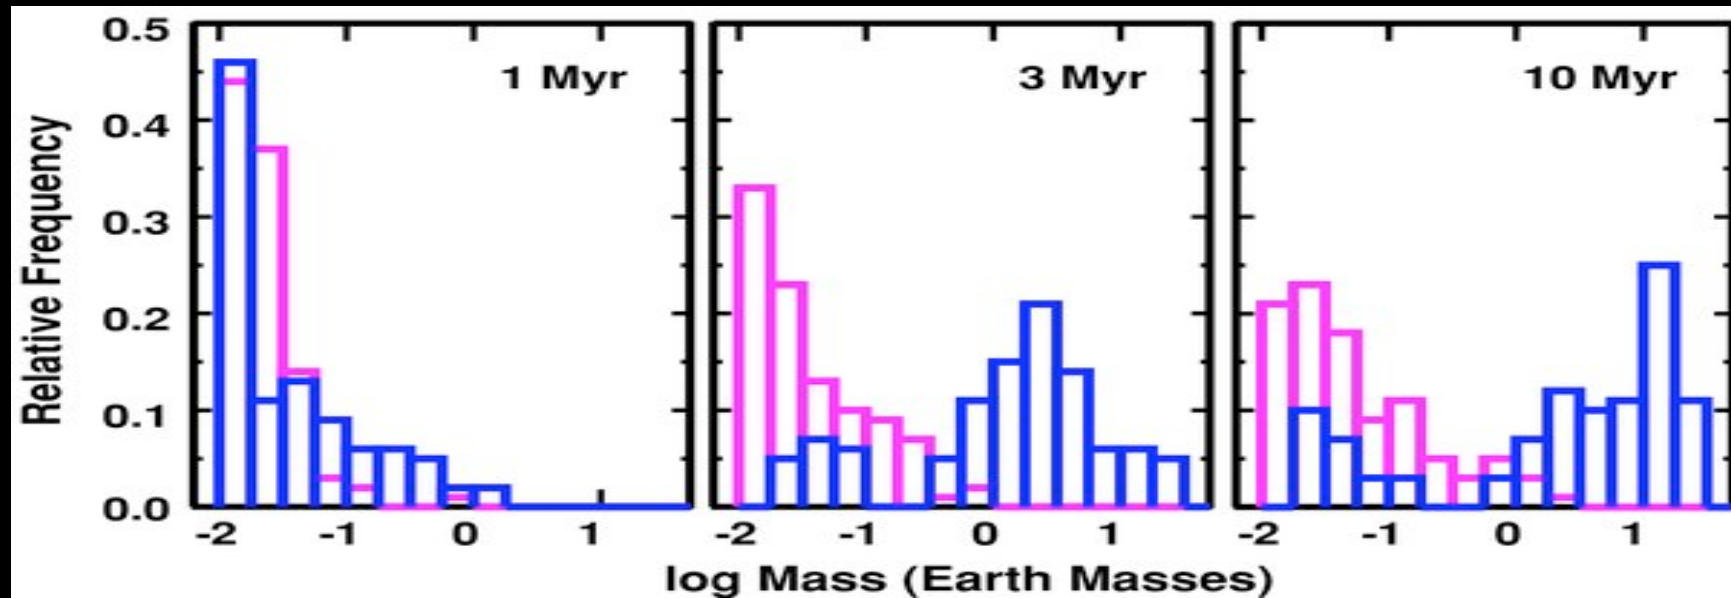

Timescale for gas giant planet formation:

MS A stars: 2.5 Myr or less; Solar/subsolar-mass stars: 5 Myr or less

Less time for A stars, yet planets around A stars are frequent (e.g. Johnson et al. 2007) → formation must be very efficient

1c. Gas Giant Planet Formation

Rapid, successful core accretion: Jovian planets forming at ~ 5 AU by ~ 3 Myr (Kenyon and Bromley 2009). Need tiny (< 10 – 100 m) planetesimals and gas \rightarrow lots of slow-moving fragments

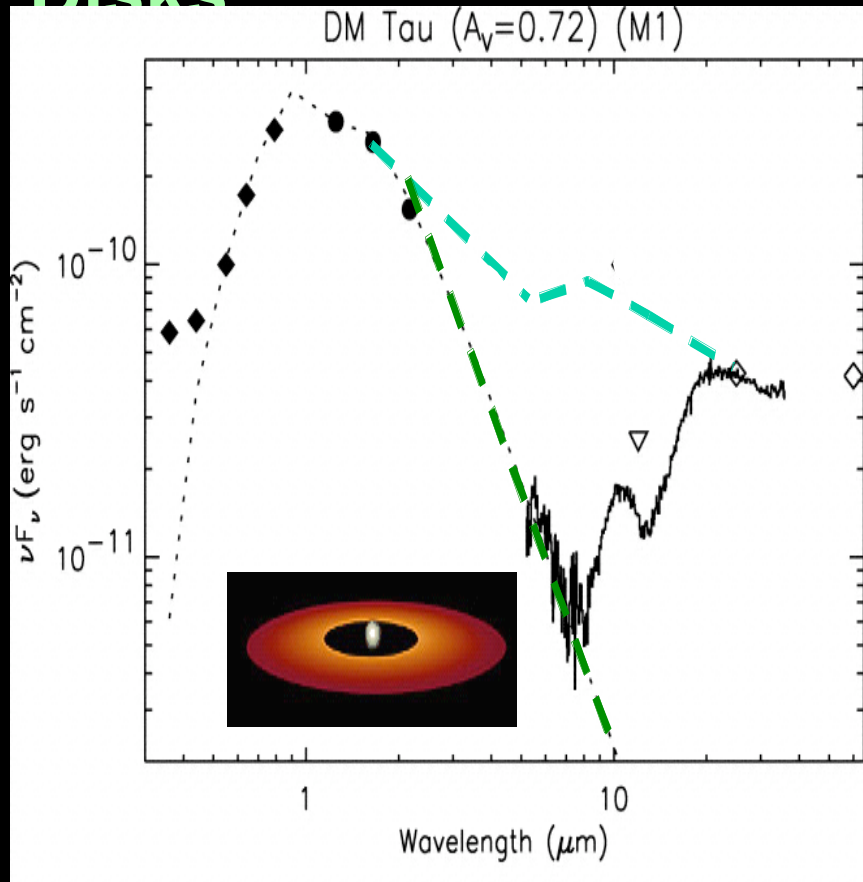

\rightarrow 2.5 Myr ?

Can HR 8799 bcd and Fomalhaut b form by core accretion?
Very difficult!

2a. The Lifetimes and Morphologies of Transition Disks

Mass &
Time

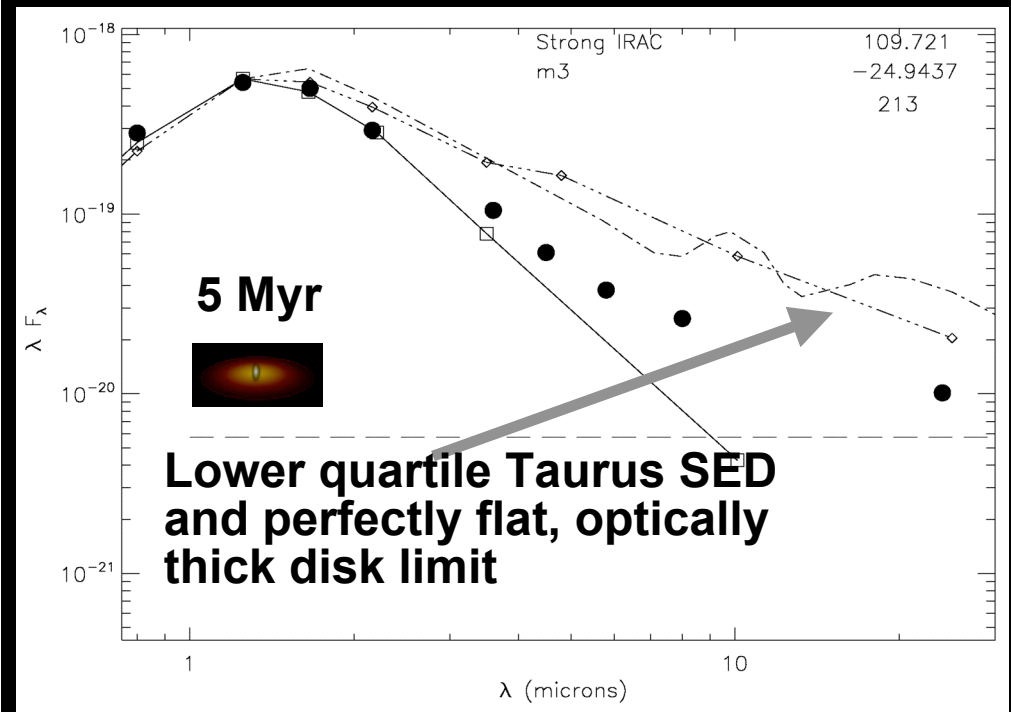

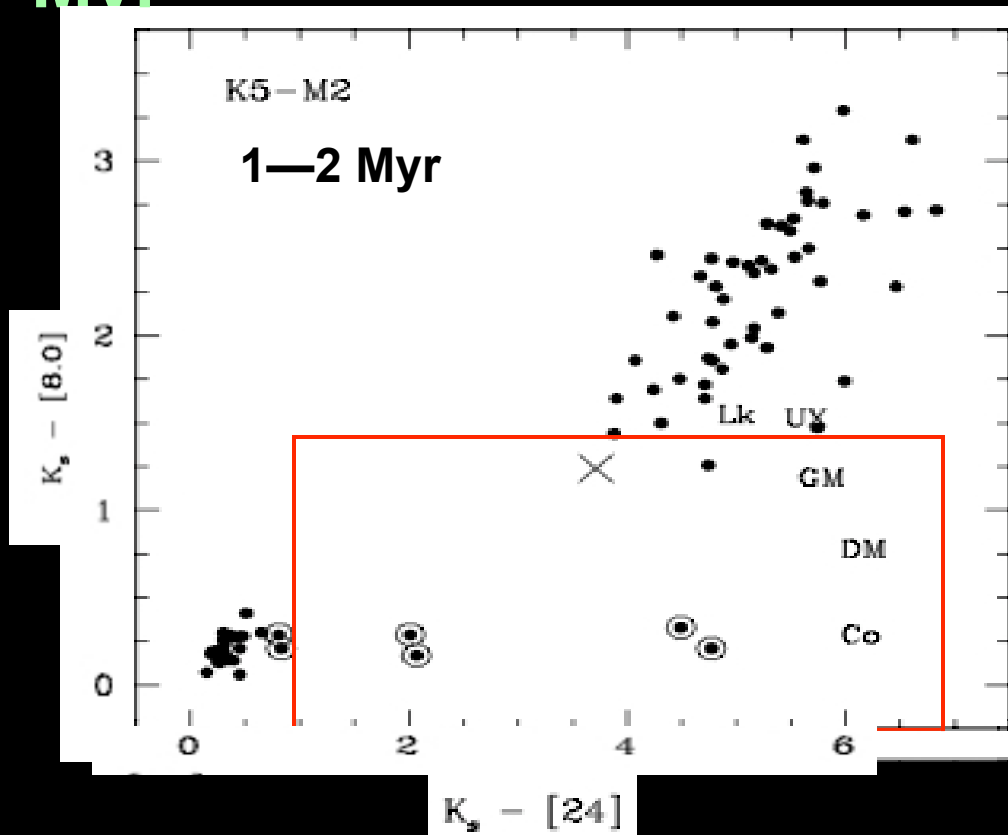

Transition disks = disk
with inner regions
depleted of dust (and
gas?)

Based on Taurus data,
transition timescale is ~
0.01 - 0.1 Myr

Another path: disks that are
depleted more
"homologously"

2b. Relative Fraction of Transitional Disks at 1 and 5 Myr

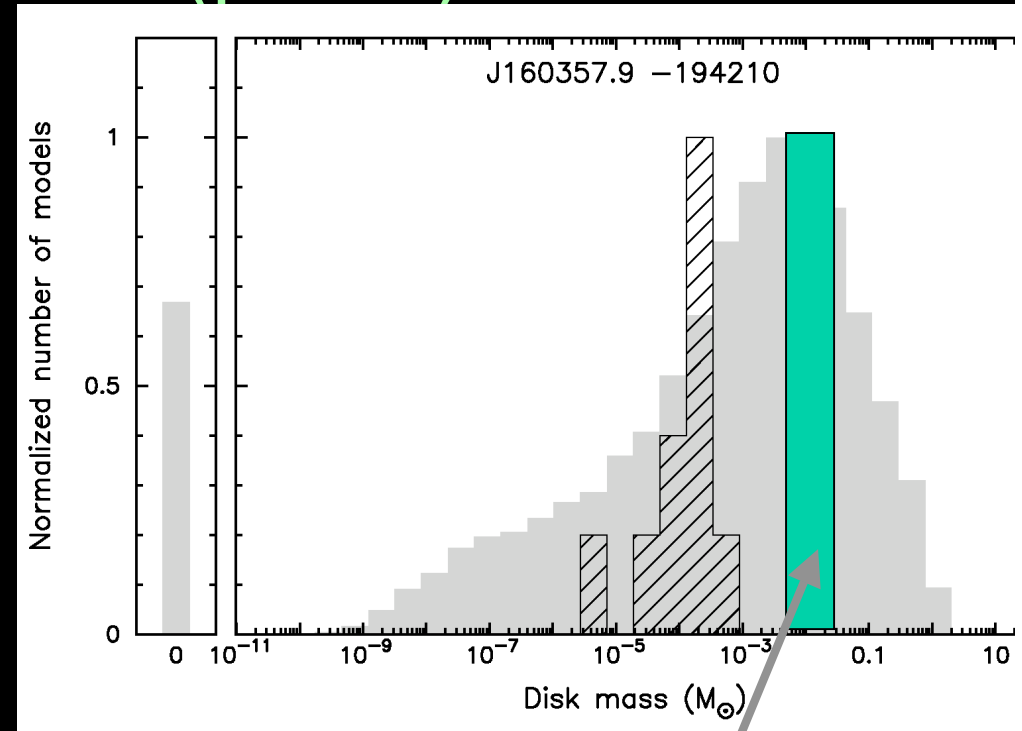

For Taurus, about
5—15% of disks are
transitional
→ very short transition
timescale (0.1 Myr)?

NO : In NGC 2362, 1) two
types of transitional disks
(many are 'homologously
depleted': have lost
substantial dust mass), 2) >
50% of disks are transitional

Currie & Lada et al. 2009

Why 'Homologously Depleted' Disks are bona fide transitional disks, not just flat Taurus-like (primordial) disks (part 2)

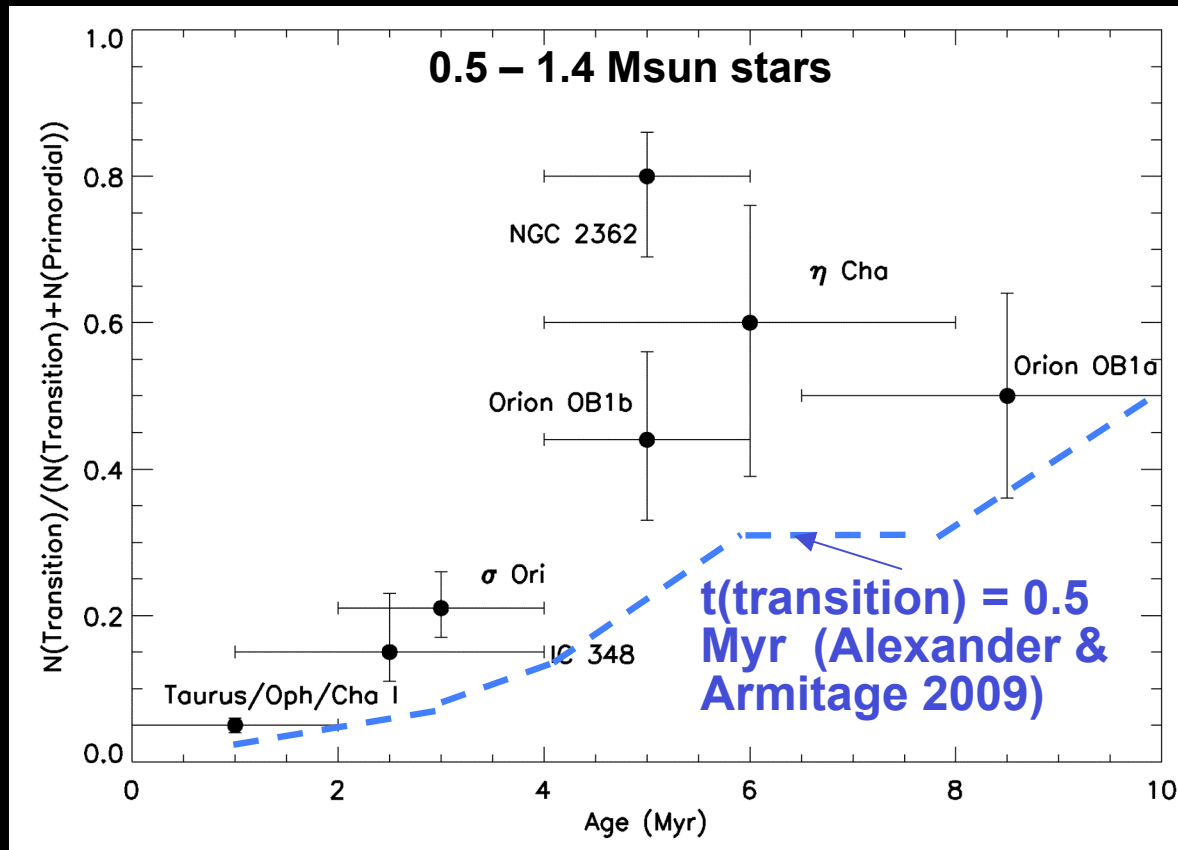

Primordial
disks in
Taurus

M_{disk} (submm) < 1 M_{jupiter}:
<10x less massive than some
transition disks in Taurus (e.g.
Najita et al. 2007)

Best-fit M_{disk} from
Robitaille models ~
0.1 M_{jupiter} (Currie
et al. 2010b)

2c. Relative Fraction of Transition Disks Increases with Age

Frequency vs. time not consistent with rapid (0.01—0.1 Myr) dispersal timescale: ~1 Myr more plausible planetary disks “die a slow death”

Not consistent with “UV Switch” Model (rapid photoevaporation; Clarke et al. 2001)

Not consistent with gap-opening planets with high disk viscosity?

But photoevaporation in general not “ruled out”: (e.g. Gorti et al. 2009; Alexander & Armitage 2009, etc.) and *does* occur (e.g. Pascucci and Sterzik 2009)

2d. Disk Evolution

(New)

Transition Disks

Primordial Disks

(~2-5 Myr)

“Homologously Depleted” Disk

(~ 1 Myr?)

Debris Disks

(~ 2-5 Myr)

Disk with Inner Hole/Gap
 (“Radially Depleted”
 Disk)

(~ 1 Myr?)

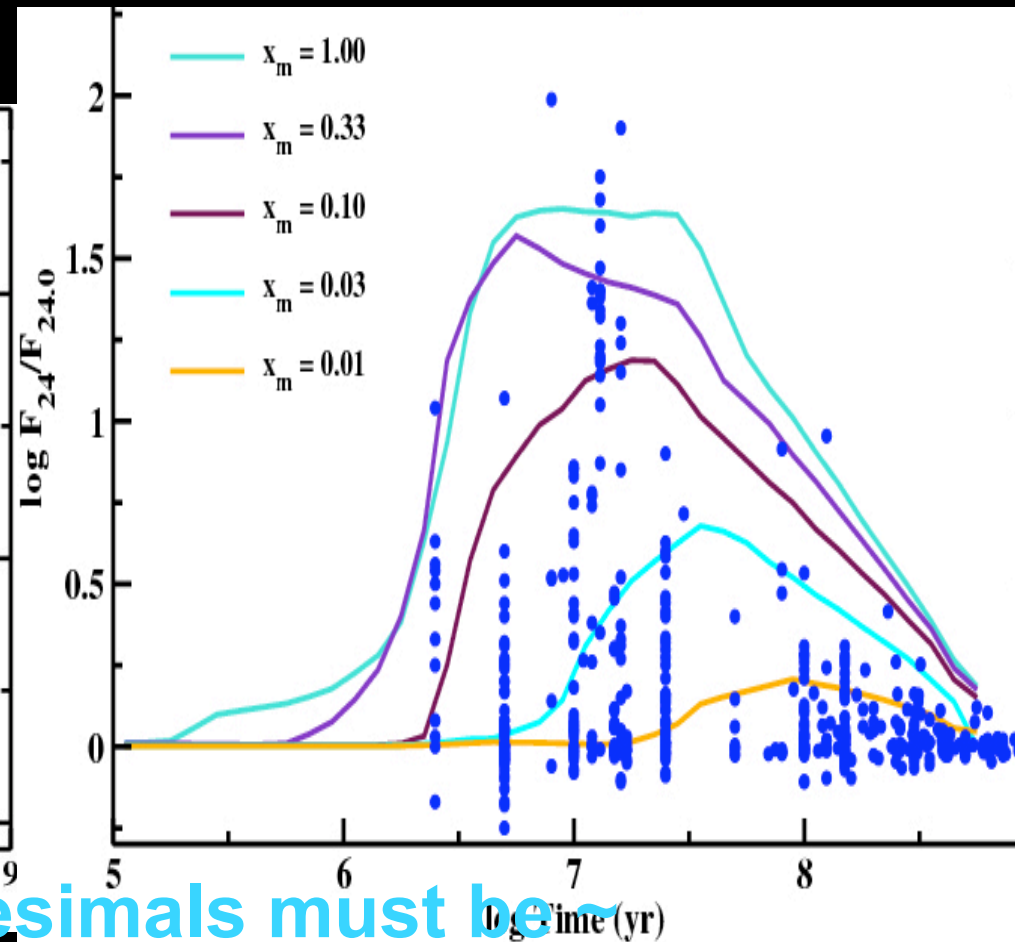

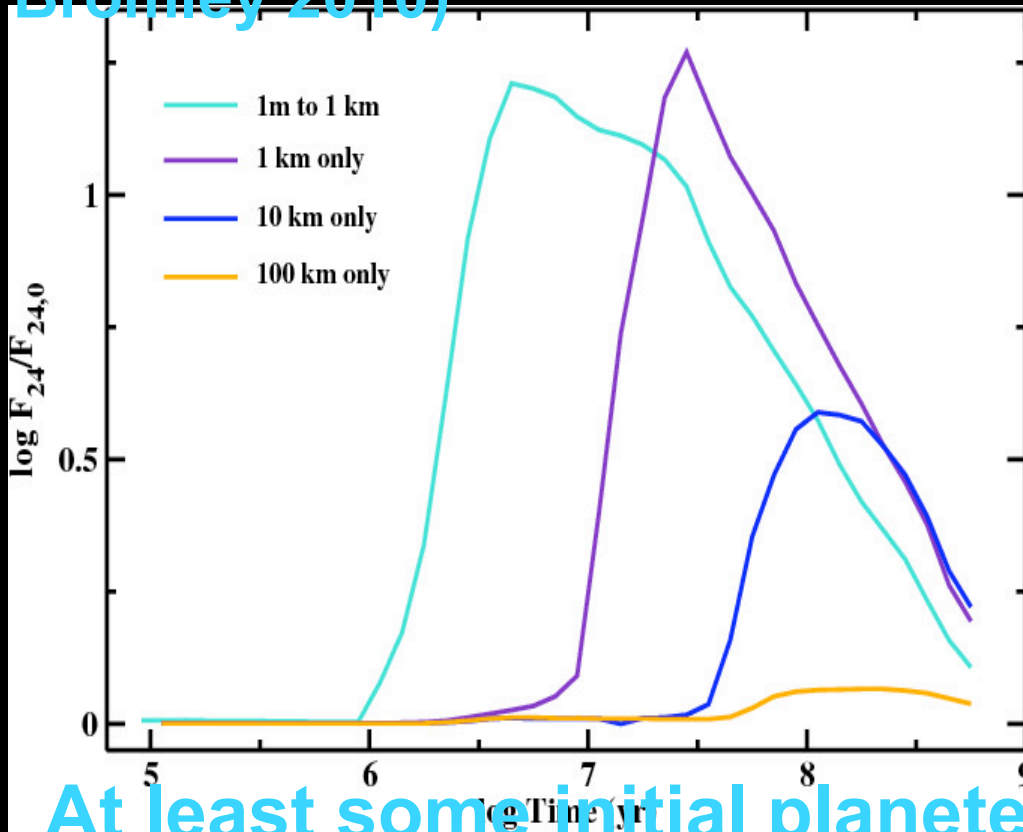

Debris Disk Evolution:

Debris Luminosity vs. Planetesimal Size

Planetesimals large \rightarrow explains
asteroid belt? (Morbidelli et al.
2009)

Different Planetesimal Sizes vs.
debris emission (Kenyon &
Bromley 2010)

Observations of MS A stars
(Currie et al. 2008)

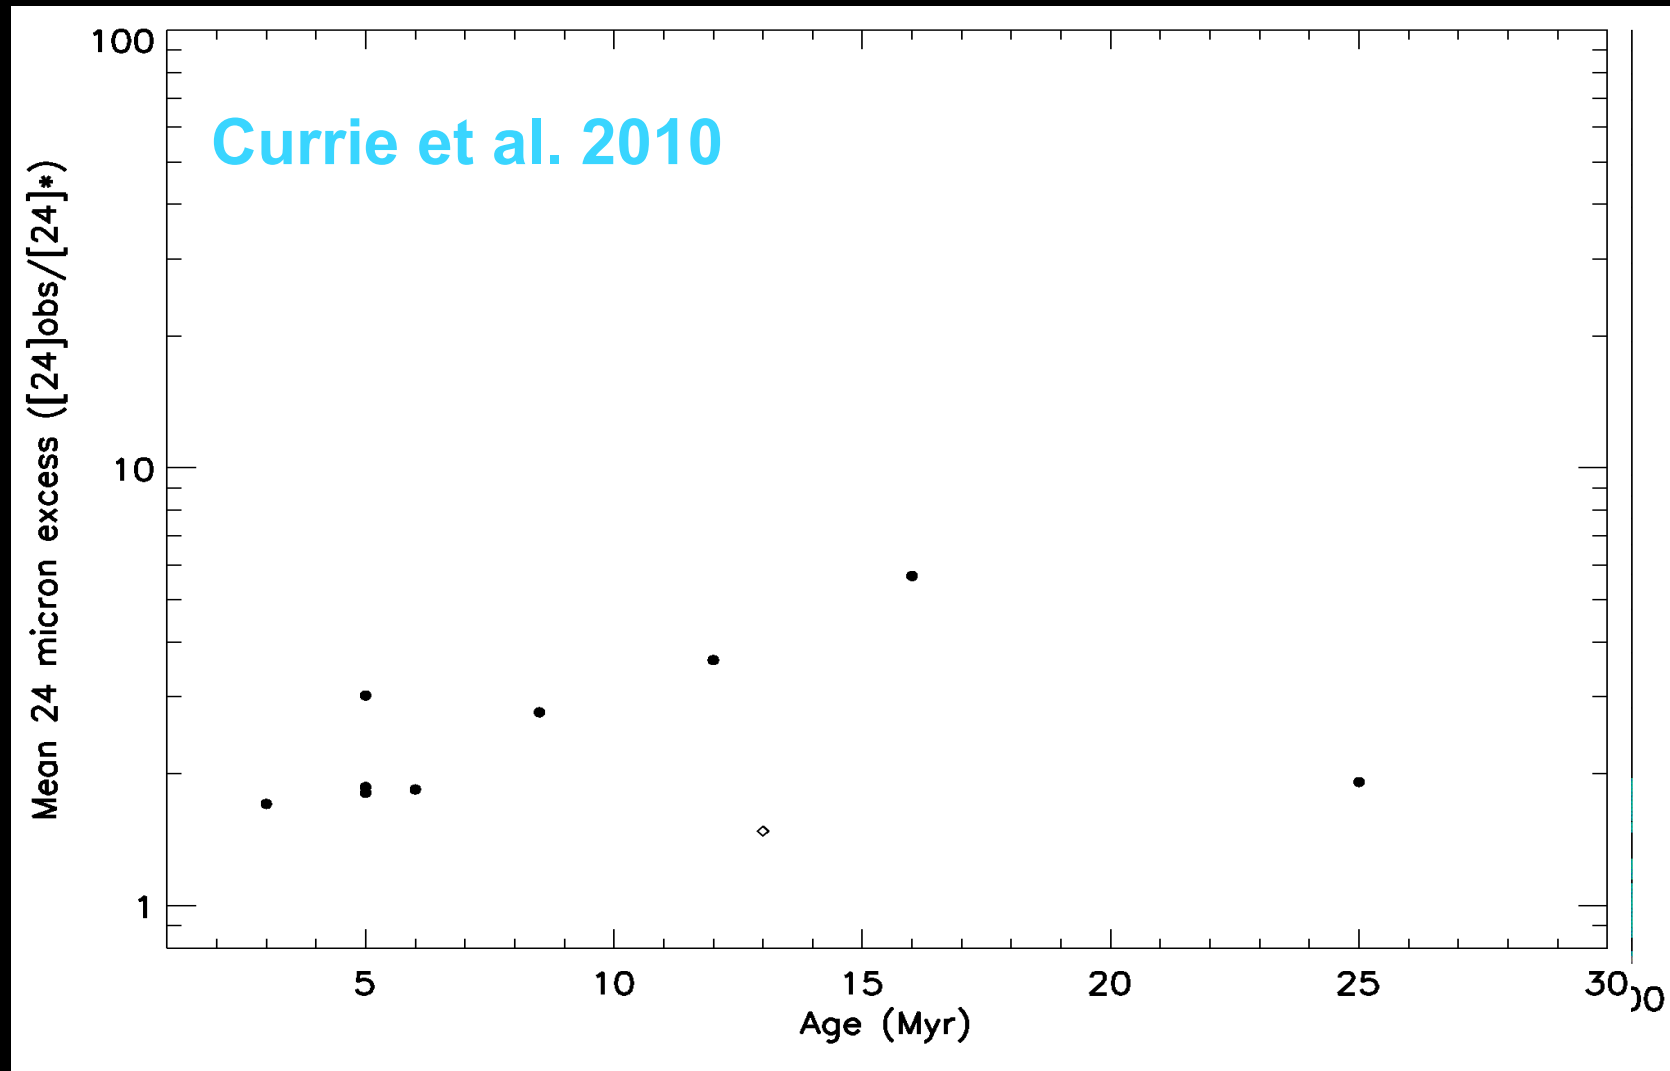

At least some initial planetesimals must be

1m—1km

Peak emission at 10—15 Myr? New data suggests

Evolution of 24 micron debris emission (Main Sequence A Stars)

Peak in debris emission at ~10-15 Myr

Due to growth of ~1000 km objects & viscous stirring?
(Kenyon and Bromley 2008; 2010)

Summary

Gas giant planet formation: < 2.5 Myr for A stars; < 5 Myr for solar-type stars. Possible if accreted planetesimals are small

Transition Disks: two morphologies, $t(\text{transition}) \sim 1$ Myr: requires slow-acting mechanism

Debris disk studies \rightarrow At least many planetesimals must be small (1m – 1km)

Evolution of debris emission may trace stages in planet formation

Data

Cluster Age (Myr) # of Stars Work
